1 User’s manual for dislocation dynamics simulation

This document tells how to operate the simulation and how to use the provided tools to analyze the output. For explanation of the physics and algorithms, see the scientific document that comes with this program.

The HTML documentation available at ./html/index.html of the package comes with a full class and files reference manual.

2 Installation
2.1 Getting the code

The code can be obtained with GIT:

\texttt{git clone git://tuomastonteri.fi/ddsim}

2.2 Compiling

Type "make" (or "./scons") at the root directory.

Compiling needs python \texttt{\geq 1.5.2}. Available libraries will be detected automatically by \texttt{Scons}. For additional parameters try "./scons –help". For more information look at the Sconstruct python file and the following examples:

- "scons ddmain" will only build program ddmain
- "scons –config=force" will recheck library and header dependencies
- "scons –clean" will clean all targets

Has been tested to compile on several unix/linux systems including:

- melkinpaasi.cs.helsinki.fi (27.1.2010)
- ruuvi.helsinki.fi (27.1.2010)
- punk.it.helsinki.fi (27.1.2010)

Does not compile on :

- kruuna.helsinki.fi (27.1.2010) lacks required Boost libraries

2.3 Libraries

Required:

- \texttt{Boost Thread} for multithreading
- \texttt{Boost Random} for random number generation
- \texttt{Boost Program_options} for command line parsing

These are found in most Linux distributions, including the one used by HUT Fyslab kvartsi and desktop computers.

Additional:

- Compiler \texttt{OpenMP} support for multithreading
- \texttt{SDL} for visualization and image saving
2.4 Installation

- ffmpeg for animation video output
- Boost Serialization for saving/loading simulation state
- Boost Iostreams for compressing and decompressing data files. Version greater or equal to 1.34.
- Boost Filesystem for platform independent directory access

2.4 Installation

Scons will create the following executables at ./bin/ directory:

- ddmain, the simulation. See Output and Running the simulation
- activ, See activ.cpp and examples at Running the simulation
- play, See play.cpp and examples at Running the simulation
- dataplot, dataplot.cpp and examples at Running the simulation

3 Output

The output of the simulation is mostly designed for the study of the PLC effect. For this particular usage it is necessary to see the full 'simulation history' and not just a few thermodynamic variables as a function of time. This makes it necessary to use binary format and compression at places to avoid too large datafiles.

3.1 Thermodynamic variables

The simulation outputs the following thermodynamic variables:

- Average strainrate of dislocations as a function of time
- Average velocity of dislocations as a function of time
- External force as a function of time
- External force as a function of accumulated strain (what is measured experimentally)

3.2 Saving and loading state

After completion or termination the simulation will output a statefile into the data directory, which holds the full state of the simulation. One can load back that particular simulation state and continue it from any computer. For using this see the help (--help) of the main executable.

The purpose of this feature is to be able to continue analyzing interesting scenarios run on computing clusters. It can also be used to stop the simulation and change parameters on the fly to eg. prepare the material in a certain way. Also useful in case of a scheduled reboot of a cluster, where the program can output its state after receiving the unix terminate signal.
3.3 Dislocation screen

- Visualizes the dislocations, solute-atoms and pinning centers in realtime on monitor
- Enabled with "-X" or "--display"

For debugging and analyzing the effect of changing input parameters
It supports mouse and key operation:

- Pause with key SPACE.
- Zoom by holding the left mouse button and dragging to choose a section. Right or middle button will reset the zoom.

3.4 Video output

- Outputs the dislocation screen to a videofile in datadirectory in .avi MPEG4 format (play with mplayer)
- Enabled with "dd -V" or "dd --video"

For saving animations of full simulations

3.5 Time-activity plots

- Outputs the strainrate of each individual Dislocation row as a function of time in custom binary format (move.dat)
- Disabled with "dd -I" or "dd --noactivity"

The purpose is to get quick overall picture on if the PLC band propagation is taking place. This would show as either correlated localized bursts of activity or random localized bursts of activity.
The data can be converted into a .bmp image and viewed with the additional tool "activ". See activ.cpp

3.6 Animation

- Outputs Dislocation animation in custom binary format, that can be viewed with tool "play". See play.cpp
- Outputs to (anim.dat)

For saving animations of full simulations
Output possible only when the number of dislocations equal the simulation y-size. Gives small filesize for accurate animation of the Dislocations. If Solute and PinningCentres need to be visualized one must use the video output instead.
For usage examples see Running the simulation
4 Running the simulation

The code has been designed so that each feature builds on the existing code rather than replacing it or 'forking' by copying to a new project and altering it. This means that each new feature also needs a new command line parameter. All possible combinations of same parameters should be valid.

4.1 Displaying help

To see the available parameters and their default values:

```
ddmain --help
```

4.2 Example 1: Analyzing drift strainrate

The simulation has been used to study the stable 'drift' strainrate of a dislocation system when a relatively small constant external force is applied. In this situation the drift strainrate as a function of external force shows a certain kind of characteristic behaviour. This provided, that the applied force is just in the right range, not too small and not too large. Too small might show zero drift and too large will 'tear'. A behaviour in line with experiments with real materials might tell something about the dynamics of this drift behaviour.

To do this one can use the rundd.py helper script to run a simulation with varying external force in some range (a BASH script would fail to provide floating point increments):

```
./rundd.py 100 1000 100 -x 50 -y 50 -N 50 --timemax 0.075 --fps=1
```

In this particular case the force is from '100' to '1000' with a step size of '100'. This particular range was determined after first running the simulation with the dislocation screen on and observing where roughly the behaviour 'tears'. Also the simulation time (0.075) was determined in the same way by observing when a somewhat steady state has been reached in these systems by looking at the (time,strainrate) plot. The --fps parameter just specifies how often the time is printed in seconds in console (or how often the graphical display is updated when switched on). Note that on average desktop the above command will take at least 30 minutes to complete. The dataplot utility can be used to visualize whether a steady drift rates really had been reached:

```
./dataplot --dataname=strainrate
```

In this case an example data is provided at ./bin/datasteady/. It can be viewed with:

```
./dataplot --datadir=./datasteady/ --dataname=strainrate
```

The example data has been sampled 10 times (repeats of the above rundd.py command line) and gave the following result (a few of the velocities were ran to 0.125 instead of 0.075):
4.2 Example 1: Analyzing drift strainrate

The strainrate is reasonably stable at 0.075, but it would have been somewhat better to run all to 0.125. Next the dataplot utility can be used to plot steady strainrate as a function of driving force as follows:

```
./dataplot --datadir=./datasteady/ --dataname=strainrate --function=d --s_use=0
```

The above command causes the program to ignore the seed as unique data identifier so an average is taken of these datapoints. It plots strainrate as a function of parameter ‘d’ or in this case force. In this case the average is taken of the last 500 points of each data to determine the steady drift rate. The result is as follows after renaming a few lines in the resulting: gnuplot.macro:
4.3 Example 2: Studying the PLC effect

The sampling is still rough, but indicates a fast growth starting at about 500 and a possibly a different kind of behaviour from zero to 500 (the drift behaviour). It might be desirable to analyze the range 0-500 in more detail with a somewhat larger than a 50x50 system.

- rundd.py is a helper script, which runs dd with varying external drives specified by minimum value, a maximum value and a step size

4.3 Example 2: Studying the PLC effect

The default values in the simulation for all the numerous parameters have been selected to be somewhat sensible for this use (more about that in the accompanying scientific document). One needs to enable constant strainrate drive and several optional outputs:

```bash
./ddmain --constdrive -A1 -V -X -z 7
```

This enables constant strainrate drive, animation, video, display and enlarges display by 7x. Running this with the default parameters until about t=1.0 can result in the following configuration:
The red and blue things are dislocations, green dots are solute atoms and the white is background. Note some artifacts in the diffusing solute clouds. These are due to an optimization whereby solutes too far away from any dislocations are not moved at all. To quickly see what dislocations have moved one can use the activity tool:

```
./activ ./data/move.[...].dat.gz
```

Which results in the following output:

The white areas are rows with the most activity and the darker it gets the less movement there was. This shows that certain groups of dislocations are frozen by the solute atoms while the others move constantly. The same can be seen from video and animation outputs:

```
./play ./data/anim.[...].dat.gz
mplayer ./data/video.[...].avi
```

More information about this use can be found at the scientific document.
4.4 Saving and loading state

By default a state file is written into the datadirectory when a simulation is terminated. This can be loaded for examination with the following command:

```bash
./ddmain --stateload ./data/state.[..].dat.gz
```

Note that the display, zoom and video has to be specified again if those outputs are desired. To actually continue writing any data additional option 'statecontinue' is needed:

```bash
./ddmain --stateload ./data/state.[..].dat.gz --statecontinue
```

The data writing will append into the existing thermodynamic output. Video files, animation files, activity and state file will be overwritten.

There are also some parameters to override options when continuing states such as 'newmaxtime'. These are stated under "State write options" in the main executable help. More can be added on need basis into the source without breaking existing state files.

4.5 Examples of specifying parameters

To run a simulation with just dislocations and a constant driving force, with screen enabled:

```bash
ddmain -d 0.1 -X
```

Just dislocations and with a constant strainrate drive:

```bash
ddmain -p -d 0.1
```

Adding relaxation time of 5000 time units:

```bash
ddmain -p -d 0.1 -R 5000
```

Just dislocations, constant strainrate drive and strain hardening:

```bash
ddmain -p -d 0.1 -H
```

Adding solute-atoms:

```bash
ddmain -S 1.0 -T_S 0.01
```

where S is the relative amount of sim area and T_S is the temperature (not in K)

Enabling video output:

```bash
ddmain --video
```

For further usage see the sections in "--help"
5 The code and algorithms

I was given some C code in 2007 involving dislocation to dislocation interaction. The current code is completely my own, modified in structure for this programming exercise from a C/C++ hybrid it was back then to a full object oriented design. Also documentation including this manual has been improved considerably.

This project has been coded with C++ using a modular (object oriented) design and principles of generic programming. The latter means to implement a functionality only once in as general way as possible, do it properly, and then use that implementation in different sorts of situations. For example, the Runge Kutta algorithm can be easily utilized in other programs and also it would not be too hard to swap in a different numerical integration algorithm. The same is true for the Datawrite class and many other components, which have been designed for general simulation use.

The classes of the project and their dependencies are illustrated in the following figure, where an arrow head points to a dependency (the graph is constructed from a hand made description and might not be 100% accurate):

Of course, entities such as a dislocation, solute and a pinning center make up a class. For example in a Dislocation class there is all the related data such as the position and accumulated strain. Additionally there is constructor to create a dislocation and public member functions to calculate forces between a dislocation and other entities and to call the numerical integration algorithm to solve the next position.

Next there are the classes Dislocations, Solute and PinningCenters. Everything related to, for example, dislocations collectively is here. This includes the data, which is all the dislocations in a linked list. Also this includes public members functions to create all dislocations, solve forces between all the dislocations and all the other entities and also to numerically integrate the dynamics.
Having all the above mentioned functionality implemented, all that is left from running a simulation is to initialize the Dislocations, Solutes and PinningCenters classes. This happens at Ddsim class. In its constructor everything is initialized and in its public member function MainLoop() the simulation is iterated. Ddsim also uses the different output classes to output data as can be seen from the figure above.

The Runge Kutta algorithm has been implemented as a template class in class RungeKutta2, where the number of dimensions can be specified as a template parameter. A Dislocation is a child class of it with one dimensional dynamics. A Solute is the same with two dimensions.

Finally, random numbers are provided by the Ranfac class. Its public member functions are thread safe and it uses one generator for each thread transparently to the user with OpenMP. The class itself is static (initialized at the beginning on main() automatically) and gets its own seed and so it can be used without any initialization. Of course, also a custom seed can be provided.

The public interfaces of all the Classes are documented in the Classes and Files section of this manual and also the full source can be browsed.

5.1 Efficiency of algorithms

This part gives an overall summary of the algorithms used from the point of view of computational efficiency.

The dislocations are stored in a linked list, because this allows easy removal in case many dislocations get annihilated. This didn’t benchmark any meaningful difference to a linear array. The forces between dislocations are solved by calculating the force from the first to the rest (and at the same time in the opposite direction, which is just negative from the other direction). Then from the second to the rest, except the first, and so on. This leads to (N-1)+(N-2)+(N-3)+..+(N-N) iterations. This is exactly \(N(N-1) - N(N-1)/2\) iterations or \(O(N^2/2 - N/2)\). There is no getting around this with \(1/r\) force.

All the solute atom data is stored in an array, because the amount is kept constant. Additionally the simulation area is divided into fixed sized blocks in the amount of X times Y (so 100^2 for 100*100). These blocks are stored in an array, where each member is a linked list of pointers to solute atom data. Now, the force between dislocations and solutes is only solved from solutes that are certain blocks away from the dislocation in a rectangle. This is also a runtime parameter. Additionally an array of booleans is kept updated, which say in which blocks solutes interacted with any dislocations the last iteration. Those solutes that weren’t in blocks that interacted are not updated or touched except to zero forces each iteration. These allow to have a huge number of solute atoms especially if most of them are in blocks that do not interact with dislocations. Just zeroing the force memory in the array of solutes is extremely cache optimal operation.

In this version of the code only the dislocation \(<->\) dislocation interaction is parallelized using Boost::threads or a modification of it called threadpool. This is just a proof of concept. The implementation is not particularly elegant unlike OpenMP, but very efficient. With two core CPU the performance increase can near 95-99% with very large dislocation systems depending on the percentage of total run time spent calculating the dislocation force function.

In principle, a new OpenMP 3.0 concept of tasks should allow to parallelize object oriented code in extremely nice fashion. Also 3.0 brings support for C++ iterators. In practice, all compilers tried failed at the start of the year 2010 to produce efficient parallel code with either features. This is what I would like to use to parallelize this project (mainly solute \(<->\) dislocation interaction).

More details about the efficiency of the code is found in the source directory.

5.2 A few thoughts on C++ for numerical physics

Good:
5.2 A few thoughts on C++ for numerical physics

- Much, much faster to code than C (mainly due to C++ standard libraries)
- Encourages the usage of standard libraries and methods instead of creating buggy ad hoc C solutions
- Clearer, more generic and expandable code when little time is spent designing the class structure
- Just as fast in executing time when properly used than any C implementation

Bad:

- Code complexity is considerably higher than in C. Especially template rich C++ looks nasty. However, advanced concept can be avoided when introducing to C++.
- Can be slow to compile
